Antimicrobial Susceptibility Testing: Critical Issues for ...

Antimicrobial susceptibility testing (AST) interpretive criteria (breakpoints and cutoffs) serve to translate numerical data (zones of inhibition and MIC values) into textual categories that provide direction to clinicians as to whether a microbial isolate is likely to respond to a given antibiotic when administered at the recommended dosing for the site of infection.

They are present around 20% of the time, depending on the risk of the patient. If the patient was in ward or an intensive care unit, it's important to implement rapid antimicrobial susceptibility testing and to have data from the rapid implementation of antimicrobial therapy. Investigating traditional and modern approaches to AST

Susceptibility tests measure antimicrobial activity against bacteria under laboratory conditions (in vitro activity), not in the patient (in vivo activity). It cannot be assumed therefore, that an antimicrobial that kills or prevents an organism from growing in vitro will be a successful treatment.

There are several issues associated within vitrosusceptibility testing of polymyx- ins, such as interpretive categories (criteria) and breakpoints, quality control (QC) strains, the reliable reference susceptibility testing method, the multicomponent com- position of polymyxins, their poor diffusion into agar, their cationic nature, the effect of polysorbate 80 (P-80), and the development of heteroresistance, as well as the impact of the medium, subcultures, and storage (81).

Susceptibility testing In vitro susceptibilities to antimicrobial agents were identified by the agar dilution method, and susceptibility profiles were identified by the minimum inhibitory concentration (MIC) interpretative breakpoint criteria according to Clinical and Laboratory Standards Institute 2016 guidelines (CLSI 2016)[2] or EUCAST 2016[3] if CLSI 2016 did not provide the specific breakpoint.

Antimicrobial Resistance Information from FDA | FDA

Antimicrobial susceptibility testing is normally conducted under conditions of normoxia, yet in tissues the amount of oxygen range between <1 and 11% oxygen, whereas in vitro experiments are normally performed in 19.95% oxygen, an artificially high concentration relative to tissue concentrations.

An important task of the clinical microbiology laboratory is the performance of antimicrobial susceptibility testing of significant bacterial isolates. The goals of testing are to detect possible drug resistance in common pathogens and to assure susceptibility to drugs of choice for particular infections.

A number of reasons have accounted for the difficulties with susceptibility testing for the polymyxins, including their multicomponent composition, poor diffusion in the agar medium, adsorption to microtiter plates, the lack of a reliable susceptibility test, the lack of a specific breakpoint from professional organizations, the synergistic effect of polysorbate 80, and the development of heteroresistance.

Unless the susceptibility testing method is seriously flawed, the usual explanation for this observation is that the study sample did not include enough drug-resistant isolates. A recent example from the literature on antifungal agents illustrates this problem well. In this study, a correlation between the response of candidemia to fluconazole (400 mg/day) was sought for 104 isolates from 68 fluconazole-treated patients.
